Ni/Photoredox-Catalyzed Enantioselective Cross-Electrophile Coupling of Styrene Oxides with Aryl Iodides

ABSTRACT: A Ni/photoredox-catalyzed enantioselective reductive coupling of styrene oxides and aryl iodides is reported. This reaction affords access to enantioenriched 2,2-diarylalcohols from racemic epoxides via a stereoconvergent mechanism. Multivariate linear regression (MVLR) analysis with 29 bioxazoline (BiOx) and biimidazoline (BiIm) ligands revealed that enantioselectivity correlates with electronic properties of the ligands, with more electron-donating ligands affording higher ee’s. Experimental and computational mechanistic studies were conducted, lending support to the hypothesis that reductive elimination is enantiodetermining and the electronic character of the ligands influences the enantioselectivity by altering the position of the transition state structure along the reaction coordinate. This study demonstrates the benefits of utilizing statistical modeling as a platform for mechanistic understanding and provides new insight into an emerging class of chiral ligands for stereoconvergent Ni and Ni/photoredox cross-coupling.

INTRODUCTION

Epoxides are among the most versatile building blocks in organic synthesis due to their availability from olefins and proclivity toward ring-opening by various nucleophiles. Moreover, advances in asymmetric catalytic epoxidation have made enantiomerically enriched epoxides useful chiral precursors for stereospecific ring-opening. Alternatively, chiral catalyst-controlled asymmetric ring-opening of epoxides represents an attractive method for enantioselective syntheses (Figure 1A). Significant and enabling advances in this area have been realized predominantly with soft or heteroatom-centered nucleophiles, such as azide, water, and cyanide. While asymmetric catalytic C–C bond formation can also be achieved using organolithium and organomagnesium reagents, these methods suffer from harsh conditions and poor functional group tolerance. Furthermore, reactions with chiral epoxide substrates proceed by kinetic resolution owing to a stereospecific ring-opening step. For both practical and fundamental reasons, development of chiral catalyst-controlled stereospecific C–C bond-forming reactions of racemic epoxides would be of high value.

Transition-metal catalyzed cross-coupling offers a mild and versatile approach to C–C bond formation with the potential to effect chiral catalyst control. Over the past two decades, our group and a number of other groups have described strategies to engage epoxides as electrophiles in Ni-catalyzed cross-coupling. Weix and co-workers reported the first enantioselective cross-electrophile coupling with meso-epoxides using a chiral titanocene cocatalyst in conjunction with a racemic Ni catalyst (Figure 1B). More recently, the Yamamoto group described the arylation of 3,4-epoxyalcohols using chiral bioxazoline (BiOx) ligands and Ni catalysis that furnishes cross-coupled products in excellent enantio- and diastereoselectivity (Figure 1B). In this reaction, a pendant alcohol directing group is required on the epoxides for high stereoiduction. These important advances notwithstanding, the discovery and development of complementary methods, particularly to address the challenge of stereoconvergent cross-coupling with racemic terminal epoxides, is necessary to expand the scope and generality of this approach.

Recently, our group reported a photoassisted reductive coupling (PARC) of racemic epoxides with aryl iodides via the merger of Ni-, Ti-, and photoredox catalysis. Mechanistic studies revealed that C–C bond formation with styrene oxides proceeds in a stereoablative manner, suggesting that the development of a stereoconvergent coupling of racemic epoxides with a chiral catalyst was mechanistically feasible. Herein, we describe a Ni/photoredox-catalyzed enantioselective cross-electrophile coupling of styrene oxides with aryl...
iodides using a chiral biimidazoline (BiIm) ligand (Figure 1C). This transformation allows facile access to enantioenriched 2,2-diarylalcohols, which could be readily derivatized to various chiral 1,1-diarylalkanes, a privileged motif in many natural products and bioactive molecules such as tolterodine and sertraline (Figure 1D). Multivariate linear regression (MVLR) analysis with BiOx and BiIm ligands revealed that the electronic character of the ligands is the main contributor to enantioinduction differences between the ligands, as opposed to steric effects, which are typically responsible for stereoselectivity in asymmetric catalytic reactions. Further experimental and computational studies were conducted to interrogate this statistical model, ultimately providing support for a nonintuitive structure-selectivity relationship that may be of use in the design of other enantioselective Ni/photoredox cross-coupling reactions.

**RESULTS AND DISCUSSION**

**Reaction Optimization.** Our optimization efforts focused on identifying an appropriate chiral ligand for the coupling of styrene oxide 1 and aryl iodide 2 using conditions derived from our prior work in racemic PARC of epoxides. Initial evaluation of common chiral amine-based bidentate ligands such as BOX, BiOx, PyrOx, QuinOx, PyBOX, and PHOX indicated that a variety of BiOx ligands, a high performing ligand class in our prior report on asymmetric reductive coupling of aziridines, offered good levels of enantioinduction (Figure S1, S2). However, the desired cross-coupled product 3 was formed in low to moderate yield. Further optimization of other reaction components using L1 as the ligand revealed that the titanocene cocatalyst required in our previously reported method is not needed in this transformation, while addition of catalytic MgCl2 as a salt additive increases the reaction yield (Table 1, entry 1−3).

Recently, chiral biimidazoline (BiIm) ligands were shown to be effective in several enantioselective Ni-catalyzed reactions such as a benzylic C−H arylation and hydroarylation of vinylarenes. Although the ligand class has not been applied to asymmetric cross-electrophile coupling, the structural similarity of BiIm and BiOx ligands, coupled with their additional site for derivatization, drew our interest. We prepared a small selection of known BiIm ligands (L4−L6) and evaluated them on our model reaction (entry 6−8). BiIm ligand L6 furnished the desired product in 66% yield and 89% ee. Performing the reaction in a photoreactor further improved the yield to 70% with a slight increase in enantioselectivity to 91% ee (entry 9). Control experiments indicated that Ni, ligand, photocatalyst, triethylamine (reductant), and light are required for the transformation (entry 10, 11a-d). We also found that the use of Ir[dF(CF3)ppy]2(dtbbpy))PF6 in place of 1,2,3,5-tetrakis(carbazol-9-yl)-4,6-dicyanobenzene (4CzIPN) delivered the product in similar yield and enantioselectivity.
consistent with their similar excited state and ground state potentials (Figure S4).  

**Substrate Scope.** With the optimized reaction conditions, we examined the reaction scope with respect to aryl iodides (Table 2). A wide range of para-substituted electron-rich and electron-deficient aryl iodides (3–9) underwent coupling in high enantioselectivity. In general, more electron-deficient aryl iodides afforded higher yields than electron-rich substrates. The reaction tolerates aryl iodides containing chlorine (5), pinacol boronic ester (9), and protic acetamide (8) groups, all of which may serve as functional group handles for further diversification. Nitrogen- and oxygen-containing heterocycles such as 2,3-dihydrobenzofuran (14), substituted pyridines (15–17), and quinoline (18) are also well tolerated, demonstrating the potential for this protocol to be used in the synthesis of bioactive compounds. Additionally, while meta-substituted aryl iodides (10–12) are competent substrates under the reaction conditions, ortho-substituted aryl iodides delivered trace product presumably because steric hindrance of the electrophile deters productive chemistry.

Next, we proceeded to examine the scope of styrene oxides (Table 3). A wide range of meta- and para-substituted styrene oxides with electron-donating and electron-withdrawing functionalities (19–25) were compatible under the reaction conditions, generating products in moderate to good yield and ee’s. Sterically hindered 2(o-tolyl)oxirane (26) underwent cross-coupling, albeit in lower yield and enantioselectivity. Nevertheless, the compatibility of ortho-substitution on the styrene oxide offers a strategic alternative to the limitation in the aryl iodide scope.

**Mechanistic Investigations.** Previous Ni-catalyzed cross-coupling reactions of epoxides have been proposed to proceed by either (a) Ti-mediated radical ring-opening of the epoxide, (b) oxidative addition of Ni to the epoxide, or (c) via the intermediacy of a halohydrin generated by nucleophilic ring-opening of epoxides with exogenous or in situ-generated salt additives. Since a titanocene cocatalyst is not required for this enantioselective reaction, we sought to interrogate the impact of its omission on the reaction mechanism.

As evidence of the stereocentric nature of the reaction, subjecting both R and S enantiomers of styrene oxide 1 to the standard reaction conditions generated the enantioenriched product 3 in 63/75% yield and 91/91% ee, respectively (Figure 2A). To evaluate the alternative pathways for styrene oxide activation (b and c), we first performed competition experiments between 2-iodotoluene and styrene oxide with [dtbbpy]Ni0(COD) (see SI). This experiment showed that aryl iodide undergoes exclusive oxidative addition to Ni(0), providing evidence against the former mechanism. As evidence in favor of the intermediacy of halohydrin, we subjected bromohydrin 27 to the standard reaction conditions in place of styrene oxide. Cross-coupled product 3 was obtained in enantioselectivity identical to that obtained in the model reaction with styrene oxide, albeit in lower yield (Figure 2B). Furthermore, subjecting a substoichiometric amount (0.1 equiv) of bromohydrin in the presence of 2(o-tolyl)oxirane (0.9 equiv) yielded the corresponding products in 4% and 38% yield, respectively, suggesting that halohydrin is likely an on-cycle intermediate (Figure S15).

On the basis of these studies, a Ni(0)/Ni(II)/Ni(III)/Ni(I) catalytic cycle involving a halohydrin intermediate is proposed (Figure 2C). Oxidative addition of aryl iodide to Ni(0) 28 generates Ni(II) species 29. At the same time, nucleophilic halide ring-opening of epoxide 1 by in situ generated HX (X = Cl, Br, I from MgCl2, NiBr2·diglyme, and aryl iodide, respectively) forms the halohydrin intermediate, which can undergo either single-electron transfer (SET) (with either 32 or 4CzIPN) or halogen atom abstraction or HAA (with 32) to generate the corresponding secondary radical 30.

radical can then be trapped by 29 to form Ni(III) species 31, followed by reductive elimination to afford the cross-coupled product 3 and Ni(I) species 32. The Ni(0) catalyst 28 can then be regenerated by reduction of 32 by 4CzIPN− (PC+/PC− = −1.24 vs SCE, Ni(I)/Ni(0) = −1.17 vs SCE), which was generated via reductive quenching with Et3N (PC+/*PC− = +1.43 vs SCE, Et3N+/Et3N = +0.93 vs SCE).22

**Figure 2. Mechanistic Studies.**

N-Ts aziridines 34 under the standard reaction conditions afforded the amine product 36 in 48% yield and 83% ee (Figure 3B). These results demonstrate the potential of this single reaction protocol to extend beyond styrene oxides and aryl iodides to access diverse chemical scaffolds bearing chiral 1,1-diaryl motifs.

**Model Development.** In a prior report from our group on Ni-catalyzed enantioselective reductive coupling of aziridines, we performed MVLR analysis in collaboration with the Sigman lab using 17 BiOx ligands.13 Since a 1,1-diarylmethane stereocenter is generated in both the epoxide and aziridine coupling reactions, we questioned whether similar effects might apply in the current study. We therefore sought to use statistical and computational tools to understand the key structural features of the BiIm ligands that influence enantioselectivity in the epoxide coupling, and through accompanying mechanistic studies, shed light on aspects of the reaction mechanism that are otherwise difficult to evaluate. To do so, we gathered enantioselectivity data from an extended scope of BiOx and BiIm ligands, generated computationally derived features of the ligands, and performed MVLR analysis.24

A total of 20 BiOx and 9 BiIm ligands with diverse structure were evaluated under the reaction conditions shown in Figure 4A. We selected a number of parameters such as Sterimol values, molecular charges, and vibrational descriptors to describe the steric and electronic properties of the ligands. Ground state structures were calculated by DFT at the M06-2X/def2TZVP25 level of theory for three different coordination states of the ligands: the free ligand which was used in the aziridine study, a tetrahedral L*NiF2 complex that serves as the most cost-effective surrogate to restrict the flexibility of the ligand, and a square planar L*Ni(p-tolyl)Cl complex which resembles possible on-cycle species in the catalytic cycle (Figure 4B).26 Subsequently, features were acquired from these structures and were related to the enantioselectivity (expressed as ΔΔG‡) in the MVLR analysis. By comparing models built from molecular descriptors extracted from different representations of the ligand, we sought to probe the structural complexity and associated computational cost of ligand representation sufficient to create a statistically robust descriptive model.

To assess predictive ability of a statistical model, leave-one-out and leave-p-out cross-validation are commonly used, especially in the context of small data sets. However, such

![Figure 3. Expansion of scope.](https://doi.org/10.1021/jacs.1c08105)
methods may yield seemingly good performance metrics as an overwhelming majority of the data set is used to train the model.\textsuperscript{27} Instead, we employed a repeated stratified nested cross-validation method consisting of two cross-validation loops wherein the data was divided into train-validation/test splits and the inner loop is used to select regressor features (Figure 4B). This method has been shown to provide an almost unbiased estimate of true performance error in the identification of a robust predictive model.\textsuperscript{28}

The best-performing model for each ligand representation was selected based on the number of times that model appeared to rank the highest (performance evaluated by RMSE) among the outer folds (Figure 4C). For L*Ni(p-tolyl)Cl complex, the final linear regression model (adj. $R^2 = 0.74$) consists of three independent parameters: $\text{NBO}_\text{NI}$ (average NBO partial charge of the oxazoline/imidazoline nitrogen atoms), $\text{NBO}_\text{C4}$ (average NBO partial charge of carbon atoms adjacent to the oxazoline/imidazoline ring), and Pol (polarizability). Similarly, the three-parameter models for the L*NiF$_2$ and free ligand representations exhibit at least two electronic parameters, highlighting the importance of ligand electronic character on the enantioselectivity. However, these models performed worse, giving adj. $R^2$ of 0.69 and 0.68, respectively.

We also subjected each model to a 5 × 2 cross-validation test to compare model performance across different coordination states (See SI).\textsuperscript{29} Overall, while more precise descriptors can
be obtained from L\(^8\)Ni(p-toly)Cl, our studies indicate that the free ligand descriptors are sufficient in constructing a descriptive model, thereby saving computational cost.

Since the models were acquired from scaled parameters, the magnitude and sign of the coefficients can give information about the effects of the features. For the L\(^8\)Ni(p-toly)Cl model, enantioselectivity is largely governed by electronic effects, with more electron-donating ligands delivering higher levels of enantioselectivity (Figure 4C, middle). Enantioselectivity is negatively correlated to polarizability.\(^{30}\) To better visualize the features, we performed dimensionality reduction using principal component analysis (PCA) and plotted the data to show clusters based on their similarity (Figure 4C, right). We found that BiOx and BiIm ligands are separated by PC1 (46%) whose loadings are highly weighted toward electronic features, whereas PC2 (14%) splits BiOx into two clusters—BnBiOx and non-BnBiOx—based mostly on polarizability and steric features.

**Eyring Analysis.** Finally, we sought to investigate how the electronic character of the ligands might influence enantioselectivity and experimentally validate the model. A seminal report by Jacobsen and co-workers demonstrated that more electron-donating Mn-salen catalysts led to higher enantioselectivity in an asymmetric epoxidation reaction as a result of a later, more product-like transition state structure in accordance with Hammond’s postulate.\(^{31}\) This prompted us to examine if a similar phenomenon was occurring in our system. An Eyring analysis was performed to determine the \(\Delta\Delta H^\ddagger\) and \(\Delta\Delta S^\ddagger\) between the major and minor diastereomeric transition states leading to both enanlitomic products. Energetic parameters were obtained on the model reaction using a systematic series of electronically distinct Bilm (L6–L8) and BiOx ligands (L9, L1) from 0 to 60 °C. We found that the enthalpic component (\(\Delta\Delta H^\ddagger\)) of these reactions exhibits an upward trend with more electron-donating ligands, while the entropic contribution (\(\Delta\Delta S^\ddagger\)) does not show a clear trend (Figure 5A). In addition, the experimental \(\Delta\Delta H^\ddagger\) is highly correlated with the calculated molecular charge feature NBOs (\(R^2 = 0.96\)), indicating that more electron-rich ligands within this study rely on enthalpic factors to afford high enantioselectivity and providing experimental validation for the statistical modeling (Figure 5B). The increasing magnitude of the differential enthalpy in the more electron-rich ligands is consistent with their accessing later transition state structures with more stabilizing (or destabilizing) interactions.

**Computational Analysis.** Prior computational studies of related coupling reactions have suggested that either reductive elimination from Ni(III) or radical addition to tetrahedral Ni(II) is the enantiodetermining step.\(^{32,33}\) In terms of substrate identity, this present work is more analogous to the system studied by Gutierrez, Kozlowski, and Molander where reductive elimination is enantiodetermining. In this case, a more electron-donating ligand would be expected to better stabilize Ni(III) leading to a less exergic step and a later transition state structure according to the Hammond postulate. By contrast, the opposite trend might be expected if radical addition is stereodetermining as more electron-donating ligands could result in a less endergic reaction to generate a stabilized Ni(III) species.

To interrogate these two possibilities, we performed computational analysis of the Ni catalytic cycle using L6 as ligand and bromobenzene and styrene oxide as substrates. Geometry optimization was performed at the UB3LYP functional and 6-31G(d) basis set. To compare energetics, we performed single point calculations of optimized structures using the UB3LYP-D3/6-311+G(d,p) level of theory with solvent correction (SMD solvation model in THF). Exhaustive conformational searches were performed for all intermediates to determine the lowest energy profile. Calculations showed that the singlet square planar Ni(II) generated from oxidative addition of aryl halide to Ni(0) can undergo intersystem crossing to form a triplet tetrahedral Ni(II) B that is 2.7 kcal/mol downhill in energy, similar to results from prior computational work by Gutierrez and Chu (Figure 6A).\(^{33}\) The alkyl radical can then be intercepted by B to generate trigonal bipyramidal Ni(III) C, followed by C–C bond formation via reductive elimination to afford the coupled product and Ni(I) D. The generation of a square pyramidal Ni(III) C’ proposed by Kozlowski and Molander was also considered, but the relevant transition states were found to be energetically less favorable (see S1). Calculations showed that the energy for the reductive elimination transition state C-TS is higher than the energy for the radical addition step B-TS (Figure 6B). This suggests that reductive elimination is the rate- and stereodetermining step,
in agreement with our initial hypothesis. To gain insight into the origin of stereoselectivity, we calculated the minor diastereomeric reductive elimination transition state \( C-TS-R \), which was found to be 1.7 kcal/mol uphill in energy compared to \( C-TS-S \). This energetic difference translates to 89% ee, in good agreement with the experimentally observed ee (91%) for a similar product. Noncovalent interaction (NCI) analysis revealed a repulsive interaction between the phenyl group on the radical and isopropyl group on the ligand in the transition state structure leading to the minor enantiomer of product. This result implies that the role of the chiral substituent in the optimal Bim ligand is tied to a repulsive interaction in the diastereomeric transition state structure. In addition, the statistical modeling showed that the enantioselectivity difference between the ligands is mostly governed by electronic effects, leading to positional control of the transition states.\(^3\)\(^4\) This effect would be hard to discern otherwise given the cost of performing transition state calculations for many different large ligand systems. Therefore, the statistical modeling and computational study have proven to be complementary in providing useful mechanistic insights to a complex catalytic system.

**CONCLUSIONS**

In conclusion, we have developed a Ni/photoredox catalyzed stereoconvergent coupling of styrene oxides with aryl iodides, allowing direct access to chiral 2,2-diarylalcohols in high enantioselectivity. Our study highlights the use of statistical modeling to elucidate a structure-selectivity relationship within a class of catalytic reactions that are otherwise mechanistically quite complex. These mechanistic findings offer insight into the design of improved chiral ligands in stereoconvergent Ni and Ni/photoredox cross-coupling. Future work in this area will focus on expanding this analysis to compare the classes of stereoconvergent coupling reactions that make use of nickel/bimidazoline and bioxazoline systems.
